Is the Data Encryption Standard a Group? (Results of Cycling Experiments on DES)\(^1\)

Burton S. Kaliski Jr., Ronald L. Rivest, and Alan T. Sherman\(^2\)
MIT Laboratory for Computer Science, 545 Technology Square, Cambridge, MA 02139, U.S.A.

Abstract. The Data Encryption Standard (DES) defines an indexed set of permutations acting on the message space \(\mathcal{M} = \{0, 1\}^{64}\). If this set of permutations were closed under functional composition, then the two most popular proposals for strengthening DES through multiple encryption would be equivalent to single encryption. Moreover, DES would be vulnerable to a known-plaintext attack that runs in \(2^{29}\) steps on the average. It is unknown in the open literature whether or not DES has this weakness.

Two statistical tests are presented for determining if an indexed set of permutations acting on a finite message space forms a group under functional composition. The first test is a “meet-in-the-middle” algorithm which uses \(O(\sqrt{K})\) time and space, where \(K\) is the size of the key space. The second test, a novel cycling algorithm, uses the same amount of time but only a small constant amount of space. Each test yields a known-plaintext attack against any finite, deterministic cryptosystem that generates a small group.

The cycling closure test takes a pseudorandom walk in the message space until a cycle is detected. For each step of the pseudorandom walk, the previous ciphertext is encrypted under a key chosen by a pseudorandom function of the previous ciphertext. Results of the test are asymmetrical: long cycles are overwhelming evidence that the set of permutations is not a group; short cycles are strong evidence that the set of permutations has a structure different from that expected from a set of randomly chosen permutations.

Using a combination of software and special-purpose hardware, the cycling closure test was applied to DES. Experiments show, with overwhelming confidence, that DES is not a group. Additional tests confirm that DES is free of certain other gross algebraic weaknesses. But one experiment discovered fixed points of the so-called “weak-key” transformations, thereby revealing a previously unpublished additional weakness of the weak keys.

Key words. Birthday Paradox, Closed cipher, Cryptanalysis, Cryptology, Cryptography, Cycle-detection algorithm, Data Encryption Standard (DES), Finite permutation group, Idempotent cryptosystem, Multiple encryption, Pure cipher, Weak keys.

1. Introduction

On November 23, 1976, the United States National Bureau of Standards adopted the Data Encryption Standard (DES) as a federal standard for the cryptographic protection of computer data [12], [61]. Although the National Security Agency has withdrawn its support of DES, many banks and other organizations continue to use DES to protect unclassified data [34]. Despite its widespread use, numerous fundamental questions about the standard remain unanswered in the open literature. In this paper we address one such important question: "Is the set of DES transformations closed under functional composition?"

DES defines an indexed set of permutations acting on the message. \( M = \{0, 1\}^n \). There are \( M = 2^{2^n} \) messages and \( K = 2^{56} \) keys. Each key \( k \) represents a transformation \( T_k \), with inverse \( T_k^{-1} \). Let \( M = \{1, 0\}^n \) denote the set of keys.

It is important to know whether or not DES is closed since, if DES were closed, it would have the following two weaknesses. First, both sequential multiple encryption and Tuchman's multiple encryption scheme—the two most popular proposals for strengthening DES through using multiple encryption—would be equivalent to single encryption. That is, if DES were closed, then for every three keys \( i, j, k \) there would exist keys \( r, s \) such that \( T_i T_j T_k(x) = T_r(x) \) and \( T_i T_j^{-1} T_k(x) = T_s(x) \) for all messages \( x \). Even worse, DES would be vulnerable to a known-plaintext attack that runs in \( 2^{28} \) steps, on the average. Each weakness follows from the fact that the set of cryptographic transformations of any closed cipher forms a group under functional composition. For similar reasons, it is important to know if DES is pure. Although most researchers believe DES is neither closed nor pure, no one has proven this conjecture in the open literature.

To determine whether DES is a group, we developed two statistical tests. The first test is based on a "meet-in-the-middle" strategy and takes \( O(\sqrt{K}) \) time and space. The second test follows a pseudorandom walk in the message space until a cycle is detected, using \( O(\sqrt{K}) \) time and constant space. Each test yields a known-plaintext attack against any group cipher. Although we focus on DES, the methods presented here work for any finite, deterministic cryptosystem.

Using a combination of software and special-purpose hardware, we applied the cycling closure test and other related tests to DES. None of our experiments involving randomly chosen DES transformations detected any algebraic weaknesses. In particular, our data show with extremely high confidence that DES is neither closed nor pure. However, one experiment unexpectedly discovered fixed points for two of the so-called "weak-key" transformations [9], thereby revealing a previously unpublished additional weakness of the weak keys.

The body of this paper is organized in five sections. Section 2 presents a brief
overview of the cycling closure test. Section 3 presents some background information useful to understanding our results. Section 4 describes the cycling closure test and other algebraic tests in detail. Section 5 explains how the meet-in-the-middle and cycling closure tests can be modified into known-plaintext attacks against group ciphers. Section 6 summarizes and interprets our experimental results. An appendix, which gives additional detailed descriptions of our experiments, is also included.

2. An Overview of the Cycling Closure Test

This section summarizes how we applied the cycling closure test to DES to determine if DES is closed.

Let $x_0$ be any message and consider the set $S_{x_0}$ recursively defined as follows: $x_0$ is an element of $S_{x_0}$, and, for any key $k$ and any message $x \in S_{x_0}$, $T_k(x)$ is also an element of $S_{x_0}$. Thus, $S_{x_0}$ is the set of messages that can be reached through multiple encrypting $x_0$ zero or more times with arbitrary keys.

If DES acted like a set of randomly chosen permutations, then we would expect $S_{x_0} = \mathcal{M}$ and thus $|S_{x_0}| = M = 2^{56}$. However, if DES were closed, then $|S_{x_0}| \leq K = 2^{56}$, since sequential multiple encryption would be equivalent to single encryption and there are at most $K$ distinct encryption transformations. The cycling closure test computes a statistic based on the size of $S_{x_0}$.

The cycling closure test picks an initial message $x_0$ at random and then takes a pseudorandom walk in $S_{x_0}$, beginning at $x_0$. For each step of the pseudorandom walk, the previous ciphertext is encrypted under a key chosen by a pseudorandom function of the previous ciphertext. The walk continues until a cycle is detected. By the "Birthday Paradox" (see Section 3.4), the walk is expected to cycle after approximately $|S_{x_0}|^{1/2}$ steps.

More specifically, the test computes a sequence of messages $x_0, x_1, \ldots$. For each $i \geq 0$, the next message $x_{i+1}$ is computed by

$$s_{i+1} = f_{s_i}(x_i),$$

where the function $f_s : \mathcal{M} \rightarrow \mathcal{M}$ is defined by

$$f_s(x) = T_{s}(x)$$

for all messages $x \in \mathcal{M}$. The walk is guided by a deterministic, pseudorandom function $\rho : \mathcal{M} \rightarrow \mathcal{M}$ that maps messages to keys. If $\rho$ is "random," then $f_s$ acts like a random function on $S_{x_0}$.

Since $S_{x_0}$ is finite, the walk will eventually encounter the same message twice. Thereafter, the walk will remain periodic because $f_s$ is deterministic. Let $\lambda$ be the least integer such that $x_i = x_0$ for some $0 \leq \lambda < i$, and let $\mu$ be the least positive integer such that $x_{i+\mu} = x_i$. The walk is completely determined by the leader $x_0, x_1, \ldots, x_{i-1}$ and the cycle $x_i, x_{i+1}, \ldots, x_{i+\mu}$. The integers $\lambda$ and $\mu$ are called, respectively, the leader length and cycle length of the sequence $x_0, x_1, \ldots$. See Fig. 1.

To detect cycles and to compute cycle and leader lengths, we used a variation of the Sedgewick–Szymanski cycle detection algorithm [27], [49].

Results of the test are asymmetrical. Walks significantly longer than $\sqrt{K} = 2^{28}$
are strong evidence that DES is not a group. Walks significantly shorter than \( \sqrt{M = 2^{22}} \) are strong evidence that DES has a structure different from that expected from a set of randomly chosen permutations.

Our experiments detected cycles after approximately \( 2^{33} \) steps, giving overwhelming evidence that DES is not a group.

3. Background

This section presents background material helpful in understanding the rest of this paper. Section 3.1 introduces the notion of a finite, deterministic cryptosystem and explains some terminology used throughout the paper. Section 3.2 discusses the \textit{a priori} chance that DES is a group. Section 3.3 summarizes several important differences between closed ciphers and ciphers that consist of randomly chosen permutations. Section 3.4 reviews the so-called "Birthday Paradox," and Section 3.5 surveys previous work on DES relevant to this paper.

3.1. Definitions and Notation

A (finite, deterministic) cryptosystem is an ordered 4-tuple \( (X, M, G, T) \), where \( X \), \( M \), and \( G \) are finite sets called the key space, message space, and ciphertext space, and \( T : X \times M \rightarrow G \) is a transformation such that, for each \( k \in X \), the mapping \( T_k = T(k, \cdot) \) is invertible.

The order of a cryptosystem is the number of distinct transformations; the degree of a cryptosystem is the size of the message space. A cryptosystem is endomorphic if and only if the message space and ciphertext space are the same set.

Thus, for any cryptosystem \( (X, M, G, T) \), each key \( k \in X \) represents a transformation \( T_k : M \rightarrow G \). In an endomorphic cryptosystem, each key represents a permutation on \( M \). A cryptosystem is faithful if and only if every key represents a distinct transformation.

For any cryptosystem \( \Pi = (X, M, G, T) \), let \( F \Pi = \{ T_k : k \in X \} \) be the set of all encryption transformations, and, whenever \( \Pi \) is endomorphic, let \( G \Pi = \langle F \Pi \rangle \) be
the group generated by $\mathcal{F}_n$ under functional composition. For any transformation $T_i \in \mathcal{F}_n$, let $T_i^{-1}$ denote the inverse of $T_i$. In addition, let $K = |\mathcal{K}|$ be the size of the key space; let $M = |\mathcal{M}|$ be the degree of $\mathcal{M}$; and let $m = |\mathcal{F}_n|$ be the order of $\Pi$.

Whenever the meaning is clear, we will omit the subscript $\Pi$.

Let $I$ be the identity permutation on $\mathcal{M}$, and let $\mathcal{A}_\mathcal{M}$ and $\mathcal{S}_\mathcal{M}$ be, respectively, the alternating group and symmetric group on $\mathcal{M}$. For any permutations $g, h$ on $\mathcal{M}$ we denote the composition of $g$ and $h$ by $gh = g[h(\cdot)]$. For any permutations $g_1, g_2, \ldots, g_n$, let $\langle g_1, g_2, \ldots, g_n \rangle$ denote the group generated by $g_1, g_2, \ldots, g_n$ under functional composition.

To analyze the closure tests it is useful to introduce the following standard terminology from permutation group theory [55], [46], [53]. Let $G$ be any subgroup of $\mathcal{S}_\mathcal{M}$, and let $x$ be any message in $\mathcal{M}$. The order of $G$ is the number of elements in $G$; the degree of $G$ is the cardinality of $\mathcal{M}$. For any $g \in \mathcal{S}_\mathcal{M}$, the order of $g$ is the order of $\langle g \rangle$.

The $G$-orbit of $x$ is the set $G$-orbit($x$) = $\{g(x): g \in G\}$. For any permutation $g \in \mathcal{S}_\mathcal{M}$, we will write $g$-orbit($x$) to denote the $\langle g \rangle$-orbit of $x$. If $f$ is any function (not necessarily a permutation) and if $x \in \text{Domain}(f)$, we define the $f$-closure of $x$ to be the set $f$-closure($x$) = $\{f^i(x): i \geq 0\}$.

The $G$-stabilizer of $x$ is the set $H_x = \{g \in G: g(x) = x\}$, which forms a subgroup of $G$.

For any subset of permutations $S \subseteq \mathcal{S}_\mathcal{M}$ and for any subset of messages $X \subseteq \mathcal{M}$, we say $S$ acts transitively on $X$ if and only if, for every pair of messages $x, y \in X$, there exists some transformation $g \in S$ such that $g(x) = y$.

Let $\Pi = (\mathcal{X}, \mathcal{M}, \mathcal{K}, T)$ be any finite deterministic cryptosystem. $\Pi$ is closed if and only if its set of encryption transformations is closed under functional composition, i.e., if and only if for every two keys $i, j \in \mathcal{K}$ there exists a key $k \in \mathcal{K}$ such that $T^i_j = T_k$. Since every finite cancellation semigroup is a group [46], $\Pi$ is closed if and only if $\mathcal{F}_n$ forms a group under functional composition.

Shannon's notion of a pure cipher generalizes the idea of closure to nonendomorphism cryptosystems [48]. $\Pi$ is pure if and only if, for every three keys $i, j, k \in \mathcal{K}$, there exists a key $l \in \mathcal{K}$ such that $T^i_j T^{-1}_k = T^i_l$.

Thus, $\Pi$ is pure if and only if for every $T_i \in \mathcal{F}_n$ the set $T_i^{-1} \mathcal{F}_n$ is closed. But for any $T_i \in \mathcal{F}_n$, $T_i^{-1} \mathcal{F}_n$ is closed if and only if $T_i \mathcal{F}_n$ forms a group under functional composition. Hence, $T_i^{-1} \mathcal{F}_n$ is closed for every $T_i \in \mathcal{F}_n$ if and only if $T_i \mathcal{F}_n$ is closed for some $T_i \in \mathcal{F}_n$. Every closed cryptosystem is pure, but not every endomorphism cryptosystem is closed.\(^4\)

For any string $s \in \{0, 1\}^n$, let $\overline{s}$ denote the bitwise complement of $s$.

DES defines a particular endomorphism cryptosystem with $\mathcal{M} = \mathcal{K} = \{0, 1\}^n$ and $\mathcal{X} = \{0, 1\}^{56}$. Because DES has degree $2^{56}$, but order at most $2^{56}$, DES is pure.

---

\(^4\) Note that we are using the term closed cipher to refer to what Shannon called an idempotent cipher [48].

\(^5\) Shannon also required each transformation of a pure cipher to be equally likely.

\(^6\) The restriction of simple substitution [19] on the standard alphabet where the letter "A" is always mapped to "B" is an endomorphism system that is pure but not closed.
intransitive. It is unknown if DES is faithful, closed, or pure. It is also unknown if any DES transformation is the identity permutation.

3.2. Is DES a Group?—A Priori Beliefs

The question of whether or not DES is closed is a question about the order of the group generated by DES. Grossman and Coppersmith observed that $G_{DES} \equiv \mathcal{A}_{\mathcal{A}}$ [8], but no one has disproved the possibility that $G_{DES} = \mathcal{A}_{\mathcal{A}}$. There are several reasons to suspect DES is not closed. First, Coppersmith and Grossman proved "DES-like" permutations generate the alternating group [8]. Second, if even just two permutations are chosen at random from $\mathcal{A}_{\mathcal{A}}$, then there is an overwhelmingly chance (greater than $1 - e^{-\lambda^2}$) that these permutations generate either $\mathcal{A}_{\mathcal{A}}$ or $\mathcal{A}_{\mathcal{A}}$ [3], [16]. Third, no one has announced finding any three keys $i, j, k \in \mathcal{A}$ such that $T_i = T_j T_k$. Finally, according to a 1977 unclassified summary of a report of the Senate Select Committee on Intelligence, the National Security Agency certified that "the final DES algorithm was, to the best of their knowledge, free of any statistical or mathematical weaknesses" [64].

On the other hand, DES is not a set of randomly chosen permutations, and Coppersmith and Grossman did not prove that DES generates $\mathcal{A}_{\mathcal{A}}$. Furthermore, DES is known to have the following three regularities [12], [38], [9], [24]:

1. Complementation property. For every key $k$ and every message $x$, $T_k(x) = T_k(x)$.
2. Existence of weak keys. There exist at least four distinct keys $k$ such that $T_k^2 = I$.
3. Existence of semiweak keys. There exist at least six distinct pairs of keys $k_1 \neq k_2$ such that $T_{k_1} T_{k_2} = I$.

The last two properties, however, apparently involve only a small fraction of the total number of DES transformations. Although many people may have a strong belief that DES is not closed, there is a need for convincing objective evidence to answer this question.

3.3. Algebraic Properties of Closed and Random Ciphers

In this section we review several important differences between closed cryptosystems and cryptosystems that consist of randomly chosen permutations. These differences form the basis of the statistical closure tests.12 Since every finite cancellation semigroup is a group, any endomorphic cryptosystem is closed if and only if its set of encryption transformations forms a group under functional composition. Thus, closed ciphers have a great deal of algebraic structure. By contrast, one expects a set of randomly chosen permutations to have virtually no algebraic structure, as the following lemmas makes precise.

---

9 To see that $G_{DES} \subseteq \mathcal{A}_{\mathcal{A}}$ note that each round of DES is an even permutation.
10 See [21] for an extension of this result.
11 By "a set of randomly chosen permutations on $\mathcal{A}$" we mean a set of permutations each member of which is chosen independently, with uniform probability from $\mathcal{A}_{\mathcal{A}}$.
12 This section draws heavily from basic results in permutation group theory and from Shannon's classic paper [48], [36].
Properties of cryptosystems can be studied both by examining abstractly the set of encryption transformations and by examining how the transformations act on the message space. Lemma 3.1 captures an important difference between closed and random ciphers by focusing on a property of the set of encryption transformations. This lemma says that if a cryptosystem is closed, then for every transformation \( T_i \) there are many pairs \( T_i, T_j \) such that \( T_i T_j = T_j T_i \). However, if the cryptosystem is a random set of randomly chosen permutations, then for every transformation \( T_i \) it is unlikely to find any pair \( T_i, T_j \) such that \( T_i T_j = T_j T_i \). This lemma provides the basis of the meet-in-the-middle closure test.

**Lemma 3.1.** Let \( \Pi = (\mathcal{X}, \mathcal{M}, \mathcal{M}, T) \) be any endomorphic cryptosystem of order \( m \), and let \( k \in \mathcal{X} \) be any key. If \( \Pi \) is closed, then there are exactly \( m \) pairs of keys \( T_i, T_j \in \mathcal{F}_k \) such that \( T_i T_j = T_j T_i \). If \( \mathcal{F}_k \) is selected at random from \( \mathcal{S}_k \), then the expected number of pairs of transformations \( T_i, T_j \in \mathcal{F}_k \) such that \( T_i T_j = T_j T_i \) is \( m^2/M \).

**Proof.** Part 1: assume \( \Pi \) is closed. For every transformation \( T_i \in \mathcal{F}_k \), there is exactly one transformation \( T_j \in \mathcal{F}_k \) such that \( T_i T_j = T_k \). Part 2: assume \( \mathcal{F}_k \) is chosen at random. There are \( m^2 \) pairs \( T_i, T_j \in \mathcal{F}_k \) and each pair has a \( 1/|\mathcal{S}_k| \) chance of corresponding to \( T_k \). Moreover, these probabilities are independent.

For unfaithful cryptosystems, it is important to distinguish between drawing a transformation from the set of transformations and picking a representation of a transformation from the key space. Mathematically, it is usually more convenient to think about selecting a transformation from a set of transformations, but in practice, one must often select a transformation by choosing a key. Let \( \mathcal{F} \) be the set of cryptographic transformations in any cryptosystem with key space \( \mathcal{X} \). If \( T_i \) is selected at random from \( \mathcal{F} \), then the probability of picking any particular transformation in \( \mathcal{F} \) is exactly \( 1/m \), where \( m = |\mathcal{F}| \). However, if a key \( k \) is selected at random from \( \mathcal{X} \), then the probability that \( k \) represents any particular transformation in \( \mathcal{F} \) is between \( 1/m \) and \( 1/K \), where \( K = |\mathcal{X}| \). If the cryptosystem is unfaithful, then \( m < K \).

The next lemma describes the structure imposed on the message space by any closed cipher; specifically, Lemma 3.2 says that the orbits of any closed cipher partition the message space into transitive sets. This lemma provides the basis of the cycling closure test.

**Lemma 3.2.** Let \( \Pi = (\mathcal{X}, \mathcal{M}, \mathcal{M}, T) \) be any endomorphic cryptosystem of order \( m \). If \( \Pi \) is closed, then, for some \( 1 \leq r \leq m \), the \( \mathcal{F}_k \)-orbits of messages in \( \mathcal{M} \) partition \( \mathcal{M} \) into \( r \) mutually disjoint sets \( \mathcal{M} = B_1 \cup \cdots \cup B_r \) such that, for each \( 1 \leq i \leq r \), the following two statements hold:

1. \( \mathcal{F}_k \) acts transitively on \( B_i \).
2. \( |B_i| \) divides \( m \); in fact, for any \( x \in B_i \), \( |B_i| = m/|H_x| \), where \( H_x \) is the \( \mathcal{F}_k \)-stabilizer of \( x \).

**Proof.** (Sketch) For each \( x \in \mathcal{M} \), consider the left cosets of \( H_x \) in \( \mathcal{F} \) [46].

\( \Box \)
Corollary 3.3. If DES is closed, then DES partitions its message space into at least $2^b$ mutually disjoint transitive sets, each of size at most $2^{3b}$.

Proof. DES has degree $2^{56}$, but order at most $2^{3b}$.

The next lemma calculates the expected number of spurious decipherments of closed and random ciphers; this lemma is useful in the analysis of the tests.

Lemma 3.4. Let $\Pi = (\mathcal{K}, \mathcal{M}, \mathcal{C}, \mathcal{T})$ be any endomorphic cryptosystem of order $m$, let $p \in \mathcal{A}$ be any message, let $k \in \mathcal{K}$ be any key, and let $c = T_k(p)$. If $\Pi$ is closed, then the number of transformations that map $p$ to $c$ is $m!B_p = |H_p|$, where $B_p$ is the $\mathcal{F}_\Pi$-orbit of $p$, and $H_p$ is the $\mathcal{F}_\Pi$-stabilizer of $p$. If $\mathcal{F}_\Pi$ is chosen at random, then the expected number of transformations that map $p$ to $c$ is $m/M$.

Proof. Part 1: (sketch) by Lemma 3.2 and the fact that, for any $x, y \in B_p$, $|\{T \in \mathcal{F}_\Pi; T(x) = y\}| = |\{T \in \mathcal{F}_\Pi; T(p) = c\}|.$ Note that $|H_p| = |H_k|$. Part 2: each transformation in $\mathcal{F}_\Pi$ other than $T_k$ maps $p$ to $c$ with probability $1/M$.

3.4. The Birthday Paradox

This section briefly reviews the "Birthday Paradox" [18], which plays a dominant role in the analysis of the closure tests. The Birthday Paradox involves the question, "If $r$ people are selected at random, what is the chance that no two people will have the same birthday?" Let $p_r$ be this chance. If birthdays are independently and uniformly distributed between 1 and $m$, then

$$p_r = \frac{(m)_r}{m^r} = \frac{m!}{m^r(m-r)!} \approx e^{-r^2/(2m)}, \quad (3)$$

where $(m)_r = m(m-1)\cdots(m-r+1)$. (The approximation in equation (3), and other similar approximations, can be obtained from Stirling's formula [18], [43].) The "paradox" is that many students are surprised to learn that the probability $p_r$ is so low: with only $r = \sqrt{m}$ people, the chance is approximately $0.5$ that at least two people will have the same birthday. More precisely, for any constant $c > 0$, if $r = c\sqrt{m}$ and $m$ is sufficiently large, then $p_r \approx e^{-r^2/2}$. Thus, by choosing $r = c\sqrt{m}$ with $c$ sufficiently large, $p_r$ can be made as small as desired.

The meet-in-the-middle test uses a variation of the Birthday Paradox in which two samples $X$ and $Y$, each of size $r$, are drawn at random from a universe of $m$ elements. If $X$ and $Y$ each are drawn without replacement, and if each element is drawn independently with probability $1/m$, then the chance that $X$ and $Y$ do not intersect is exactly $(m)_r/(m)_r^2$. If $r = c\sqrt{m}$, this chance is approximately $e^{-3r^2}$.

3.5. Previous Cycling Studies on DES

To the best of our knowledge, only three other cycling experiments on DES have been reported in the open literature. These experiments were performed by Gati,
Davies and Parkin, and Hellman and Reyneri. Each of these experiments differs from our cycling closure test, and none of these previous experiments determined if DES generates a small group.

The analysis of each of these previous experiments depends heavily on the following two facts [23], [44], [32, exercise 3.1.12]. Let \( x_0 \in \mathcal{G} \) be any message. For a randomly selected function \( f \) on \( \mathcal{G} \), the expected size of the closure of \( x_0 \) is approximately \( \sqrt{M} \). (This follows from the Birthday Paradox.) But for a randomly selected permutation \( g \) on \( \mathcal{G} \), the expected size of the orbit of \( x_0 \) is approximately \( M/2 \). (See Section 4.4.3.)

Gait [20] investigated the statistical properties of pseudorandom key streams produced by DES in output-feedback mode [62]. Provided the feedback width is exactly 64 bits, each such key stream describes the orbit of a DES transformation on some initial message. In a series of software experiments, Gait computed the key stream produced by DES in output-feedback mode to at most \( 10^8 \approx 2^{20} \) places. Gait found no cycles for nonweak keys.\(^{13}\) Gait did not state what feedback width he used. Gait also proposed a new power-spectrum test for nonrandomness and applied it to each of the pseudorandom sequences he computed from nonweak keys. Gait observed that each of these sequences was considered random by his test.\(^{14}\)

Provided a feedback width of 64 bits is used, the cycling study considered by Gait is equivalent to what we call the “orbit test,” which can be viewed as a closure test (see Section 4.4.3). If DES were closed, then each of the orbits considered by Gait would have at most \( K = 2^{16} \) messages (see Lemma 3.2). Hence, observing an orbit of length greater than \( 2^{16} \) would be direct proof that DES is not closed. Although we do not do so in this paper, it is also possible to interpret the orbit test as a statistical closure test. In contrast with Gait’s experiments, we followed the orbit of a randomly chosen DES transformation for over \( 2^{26} \) steps (see Section 6).

Davies and Parkin [11], [10] and Juenevan [28] studied mathematically the cycle structure of the key stream produced in output-feedback mode. Each of these studies concluded that if DES is used in output-feedback mode with a feedback-width of less than 64 bits, then the resulting key stream will cycle in approximately \( 2^{22} \) steps, on the average (the exact expected cycle length depends slightly on the feedback width). If all 64 bits are fed back, then the expected cycle length is approximately \( 2^{23} \). The point is that the state-transition function in output-feedback mode is a permutation if and only if all 64 bits are fed back. Although Davies and Parkin did not report performing any experiments on the full DES algorithm, Davies and Parkin did run a series of experiments on DES substitutes consisting of random permutations on \( \{0, 1\}^k \). Their experimental results agreed with their theoretical predictions.

In an attempt to understand better how effectively the Hellman cryptanalytic time–space tradeoff [25] could be applied to DES, Hellman and Reyneri [26] examined the cycle structure of mappings induced by DES on the key space. Specifically, they considered mappings \( F_k : \mathcal{G} \rightarrow \mathcal{G} \) defined by \( F_k(x) = \rho(T_k(x)) \).

\(^{13}\) Since \( T_k = 1 \) for any weak key \( k \), the key stream produced in output-feedback mode with feedback width 64 bits cycles after 128 bits whenever a weak key is used.

\(^{14}\) See [17] for some recent observations on Gait’s work.
where \( p: \mathcal{M} \rightarrow \mathcal{X} \) is a projection\(^{15}\) and \( x \in \mathcal{M} \) is some fixed message. Their studies detected no significant statistical irregularities. Whether or not DES is closed, the expected cycle length of the Hellman–Reyneri experiment is about \( \sqrt{K} = 2^{32} \).

Each of these previous cycling projects studied the behavior of the powers of some indexed function (i.e., \( T_i(x_0) \) or \( F_i(k) \) for \( i = 1, 2, \ldots \)) where the index of the function was held fixed throughout the experiment: Gait and Davies and Parkin held the key fixed; Hellman and Reyneri held the message fixed. By contrast, our cycling test computes the sequence \( x_i = T_{i_0}T_{i_1}\cdots T_{i_r}(x_0) \) for \( i = 1, 2, \ldots \) where at each step \( i \) the key \( k_i \) is chosen as a pseudorandom function of the previous ciphertext \( x_{i-1} \).

4. Testing Cryptosystems for Algebraic Structure

This section describes and analyzes two statistical tests for determining if a cryptosystem is closed under functional composition. The first test is a meet-in-the-middle algorithm that uses \( O(\sqrt{K}) \) time and space. The second test is a novel cycling algorithm that uses \( O(\sqrt{K}) \) time, but only a small constant amount of space. Each test is based heavily on the Birthday Paradox (see Section 3.4). This section also describes several other related tests. Although our primary interest in these tests was to examine DES for closure, purity, and other extreme algebraic weaknesses, the tests are general in nature.

4.1. Conducting and Interpreting the Algebraic Tests

This section describes the nature of our tests, concentrating on the framework in which the tests operate and on how to interpret the test results.

4.1.1. Testing Framework. Input to each test is a finite, deterministic cryptosystem \( \Pi = (\mathcal{X}, \mathcal{M}, \mathcal{C}, T) \), with the encryption transformation \( T \) presented as a "black box." Given any key \( k \in \mathcal{K} \) and any message \( x \in \mathcal{M} \), the box computes \( T_k(x) \) and \( T_k^{-1}(x) \). No additional information about \( T \) is provided. To ensure that messages and keys are easy to detect, generate, and compare, we assume that \( \mathcal{M} = \{0, 1\}^* \), \( \mathcal{K} = \{0, 1\}^* \), and \( \mathcal{C} = \{0, 1\}^* \), for some \( u, v, w \) also provided to the test.

We assume that the sets \( \mathcal{X}, \mathcal{M}, \mathcal{C} \) are so large that they cannot be exhaustively searched; each test must proceed by examining a limited number of messages and keys. We do assume, however, that running times of \( O(\sqrt{M}), O(\sqrt{C}), \) and \( O(\sqrt{C}) \) are tractable.

4.1.2. Interpreting the Results. Each closure test computes a statistic, which can be used to calculate a measure of our relative degree of belief in the following two competing hypotheses:

- \( H_0 = \text{"}\mathcal{G} \text{ is a group.} \" \)
- \( H_1 = \text{"Each transformation } T_i \text{ was chosen independently with uniform probability from the symmetric group on } \mathcal{M}. \" \)

\(^{15}\) Hellman and Reyneri used the projection that removes each of the eight parity bits.
To compute this measure we will apply the theory of the weight of evidence, as explained by Good [40], [22].

Let E be experimental evidence produced by one trial of one of the closure tests. From this evidence we can compute the conditional probabilities \( P(E|H_0) \) and \( P(E|H_k) \), as explained in the next two sections. Note, however, that neither closure test enables us to compute \( P(E|H_0) \) or \( P(E|H_k) \), where \( H_0 \) and \( H_k \) are the complements of \( H_0 \) and \( H_k \), respectively. Thus, on the basis of experimental evidence, we would be able to conclude only that \( \Pi \) is not closed or that \( \Pi \) has a structure different from that expected from a set of randomly chosen permutations; we would not be able to conclude that \( \Pi \) is closed. In the worst case, \( \Pi \) could be closed, except for some isolated pair of keys \( a, b \) such that \( T_a T_b \) is not in \( \mathcal{S}_\Pi \), even though there exists some key \( k \) and some message \( x \) such that \( T_k x \) is \( T_k(x) \) for all messages \( x \in \mathcal{M}, x \neq x_0 \).

Initially, each person may have some (subjective) degrees of belief \( P(H_0) \) and \( P(H_k) \) in hypotheses \( H_0 \) and \( H_k \), respectively. From these initial degrees of belief, each person can compute \( O(H_0|H_k) = P(H_0)/P(H_k) \) as his or her initial odds in favor of \( H_0 \) over \( H_k \). After seeing any experimental evidence \( E \), however, each rational person should update his or her own odds in favor of \( H_0 \) over \( H_k \).

Given any evidence \( E \), a Bayesian would update his or her odds in favor of \( H_0 \) over \( H_k \) as follows:

\[
O(H_0|H_k|E) = \frac{P(E|H_0)}{P(E|H_k)} \cdot O(H_0|H_k),
\]

where \( O(H_0|H_k|E) \) is the odds in favor of \( H_0 \) as opposed to \( H_k \) given \( E \).

We encourage the reader to update his or her own odds in favor of \( H_0 \) over \( H_k \) in light of the evidence presented in Section 6.

4.2. Meet-in-the-Middle Closure Test

The meet-in-the-middle closure test (MCT) works as follows: given any endomorphic cryptosystem \( \Pi = (\mathcal{X}, \mathcal{M}, \mathcal{K}, T) \), pick any key \( k \in \mathcal{X} \) and search for keys \( a, b \in \mathcal{X} \) such that \( T_a = T_k T_b \). If \( \Pi \) is closed, then such a pair of keys \( a, b \) can be efficiently found, with high probability. If \( \mathcal{S}_\Pi \) is selected at random, then it is unlikely to find any such pair.

To search for a pair of keys \( a, b \in \mathcal{X} \) such that \( T_a = T_k T_b \), we use a standard "meet-in-the-middle" algorithm similar to that described in [37], for example. Specifically, choose 2r keys \( a_1, a_2, \ldots, a_r \) and \( b_1, b_2, \ldots, b_r \) at random and look for a pair of keys \( a_i, b_j \) for some \( 1 \leq i, j \leq r \) such that \( T_a = T_b T_a \). To find such a match, represent the cryptographic transformations by their images or preimages of some particular message. Specifically, pick any message \( p \in \mathcal{M} \), calculate \( c = T_k(p) \), and compute \( x_i = T_a(p) \) and \( y_j = T_b^{-1}(c) \) for \( 1 \leq i, j \leq r \). Then look for matches \( x_i = y_j \) by sorting the triples \( (x_i, a_i, \text{"A"}) \) and \( (y_j, b_j, \text{"B"}) \) for \( 1 \leq i, j \leq r \) on their first components. Screen out false matches by testing if \( T_a(p) = T_k T_b(p) \), for all \( 1 \leq h \leq l \), for a small number of additional messages \( p_1, p_2, \ldots, p_l \in \mathcal{M} \). (A false match is a pair of keys \( a', b' \in \mathcal{X} \) such that \( T_a(p) = T_k T_b(p) \) even though \( T_a \neq T_k T_b \).

Figure 2 summarizes this process.
input: An endomorphic cryptosystem \( \Pi = (\mathcal{X}, \mathcal{D}, \mathcal{H}, T) \) and integer control parameters \( r, l \).

begin
1. Pick \( k \in \mathcal{X} \) and \( p_1, \ldots, p_r \in \mathcal{D} \) at random. For \( i = 1 \) to \( l \), compute \( c_i = T_p(p_i) \). Let \( \mathcal{P} = \{ p_1, \ldots, p_r \} \) and \( c = c_{\mathcal{P}} \).
2. For \( i = 1 \) to \( r \), select \( a_i, b_i \in \mathcal{X} \) at random and compute \( x_i = T_{a_i}(p_i) \) and \( y_i = T_{b_i}(c) \).
3. Sort the \( \mathcal{P} \times (a_i \times b_i \times x_i) \) and \( \{ y_1, \ldots, y_r \} \) for \( 1 \leq i \leq r \) on their first components.
4. For each "match" \( a = b \) with \( 1 \leq i, j \leq r \) if \( T_{a_i}(p_i) = T_{a_j}(p_j) \) then return "Match found!".
5. return("No match found")

end

Fig. 2. Meet-in-the-middle close test (MCT).

Proposition 4.1 summarizes the main properties of MCT. Informally, Proposition 4.1 says that MCT is likely to find a match if \( \Pi \) is closed, but MCT is unlikely to find a match if \( \Pi \) is chosen at random. These facts follow from Lemma 3.1 and the Birthday Paradox.

Proposition 4.1. If \( \Pi \) is closed, then MCT finds a match with probability at least 
\[ 1 - e^{-c^2/M} \]
If \( \mathcal{F}_\Pi \) is chosen at random, then we expect MCT to find a match with probability at most \( c^2/M \).

Proof. If \( \Pi \) is closed, then for each \( 1 \leq j \leq r \), \( T_{a_j}^{-1}T_j \in \mathcal{F}_\Pi \). In this case the situation is a variation of the Birthday paradox in which we are drawing two samples \( X \) and \( Y \), each of size \( r \), from an urn containing \( m \) elements, where \( m \) is the order of \( \Pi \). The first sample consists of the transformations \( T_{a_1}, \ldots, T_{a_r} \); the second consists of the transformations \( T_{a_1}^{-1}T_{a_2}, \ldots, T_{a_1}^{-1}T_{a_r} \). If \( \Pi \) is faithful, each element is drawn with probability exactly \( 1/K \); otherwise, each element is drawn with probability at least \( 1/K \). Thus, the worst case is when \( \Pi \) is faithful. We are interested in the probability that the samples overlap.

If \( \mathcal{F}_\Pi \) is chosen at random, then by Lemma 3.1, for any \( T_j \in \mathcal{F}_\Pi \), we expect \( \mathcal{F}_\Pi \) to contain a pair \( T_{a_j}, T_{a_j}^{-1}T_j \) such that \( T_{a_j}^{-1}T_j \) with probability at most \( c^2/M \).

Thus, by choosing \( r = c^2/m \) with \( c \) sufficiently large, we can make the probability \( q_r \approx 1 - e^{-c^2/M} \) of finding a match if \( \Pi \) is closed as large as desired.

The analysis in Proposition 4.1 assumes that each sequence of keys \( a_1, \ldots, a_r \) and \( b_1, \ldots, b_r \) was drawn without replacement. If these sequences are drawn with replacement, then the expected number of samples required to obtain \( r \) distinct keys is \( K \log(K + 0.5)/(-r + 0.5) \). This situation is a variation of the "collector's problem" [18].

To carry out MCT efficiently, it is important that the expected number of false matches be small. As shown by Lemma 3.4, if \( \Pi \) is closed, then at most \( (K - 1)/B \), keys other than \( k \) map \( c \) to \( c \), where \( B_k \) is the \( \mathcal{F}_c \)-orbit of \( p \). If \( \mathcal{F}_\Pi \) is chosen at random, then we expect at most \((m - 1)/M \) key other than \( k \) to map \( p \) to \( c \). Thus, provided \( K \) is not too much larger than \( M \), the expected number of false matches is small.
MCT requires \(O(r)\) steps and \(O(r)\) words of memory. The two most time-consuming operations are generating and sorting the lists \(x_1, x_2, \ldots, x_r\) and \(y_1, y_2, \ldots, y_r\). The required number of encryptions is \(2r\) plus the number of additional evaluations used to screen out false matches. If sorting is performed in main memory using radix sort, then sorting will take \(O(r)\) machine operations; otherwise, \(O(r \log r)\) external memory operations would be needed. The main difficulty with carrying out this test on DES is the high space requirement.

Given the high space requirement of MCT, in practice it may be helpful to use variations of this test that involve time–space tradeoffs. For example, the test could be repeated several times with small values of \(r\). Alternately, the test could build a small hash table for the \(x_i\)'s and then lookup each \(y_i\) in the table without saving the \(y_i\)'s. If encryption is relatively fast in comparison to the other required operations, then it might be advantageous to save only those \(x_i\)'s that fall into some subset of the message space. Parallel variations of MCT are also possible.

### 4.3. Cycling Closure Test

Given any endomorphic cryptosystem \(\Pi = (\mathcal{X}, \mathcal{M}, \mathcal{M}, T)\), the cycling closure test (CCT) takes a pseudorandom walk in \(\mathcal{M}\) for some small \(l\). The walk continues for a specified number of steps or until a cycle is encountered. Long walks are strong evidence that \(\Pi\) is not closed; short walks are strong evidence that \(\Pi\) has a structure different from that expected from a set of randomly chosen permutations.

Specifically, CCT picks an initial vector of messages \(\hat{x}_0 \in \mathcal{M}\) at random and computes the leader length and cycle length of a sequence \(\hat{x}_0, \hat{x}_1, \ldots\). For each \(i \geq 0\), the next element in this sequence is computed by

\[
\hat{x}_{i+1} = f_\rho(\hat{x}_i),
\]

where the function \(f_\rho: \mathcal{M} \rightarrow \mathcal{M}\) is defined by

\[
f_\rho(\hat{x}) = T_{\text{seq}}(\hat{x})
\]

for all \(\hat{x} \in \mathcal{M}\). The sequence is guided by a deterministic pseudorandom function \(\rho: \mathcal{M} \rightarrow \mathcal{X}\) which maps message vectors to keys. Figure 3 summarizes this process.

(In equation (6) and throughout this section we use the convenient notation \(T_i(\hat{x})\)

```plaintext
input: An endomorphic cryptosystem \(\Pi = (\mathcal{X}, \mathcal{M}, \mathcal{M}, T)\), integer control parameters \(r_{\text{max}}\), and
a deterministic pseudorandom function \(\rho: \mathcal{M} \rightarrow \mathcal{X}\).

begin
1. Pick \(\hat{x}_0 \in \mathcal{M}\) at random.
2. Compute the leader length and cycle length of the sequence \(\hat{x}_0, \hat{x}_1, \ldots\) defined by
\[
\hat{x}_{i+1} = f_\rho(\hat{x}_i) = T_{\text{seq}}(\hat{x}_i)
\]
for all \(i \geq 0\). If no cycle is detected after \(r_{\text{max}}\) steps, then return("No cycle detected")
3. return(\(\hat{x}_0\), where \(\omega = \lambda + \mu\); \(\lambda\) is the leader length; and \(\mu\) is the cycle length computed in step 2.
end
```

Fig. 3. Cycling closure test (CCT).
to denote \((T_k(x_1), \ldots, T_k(x_t))\), for any key \(k \in \mathcal{X}\) and any message vector \(x = (x_1, \ldots, x_t) \in \mathcal{M}^t\).

To detect cycles and to compute leader lengths and cycle lengths, use the efficient algorithms described by Sedgewick and Szymanski [49] that generalize the well-known "two-finger" algorithm due to Floyd [32].

The entire cycling closure test requires \(O(\omega)\) time and a constant amount of space, where \(\omega = \lambda + \mu\) and \(\lambda\) and \(\mu\) are, respectively, the leader length and cycle length computed by the test.

The cycling closure test is similar in spirit to Pollard’s \(p\)-factoring method [41], [4]. It is also similar to the algorithm described by Sattler and Schnorr for determining the order of any element in any finite group, but Sattler and Schnorr’s algorithm requires the group to have an efficient multiplication procedure [47]. The cycling test differs from the cycling experiments performed by Gait [20] and Hellman and Reyneri [76], who held either the key or message fixed (see Section 3.5).

Proposition 4.2 states the main properties of CCT, which follow from the Birthday Paradox. In summary, CCT takes a pseudorandom walk in \(S_0\), where \(S_0 = G_{\mathcal{X}}\) orbit \(\langle x_0 \rangle\). This walk is defined by the \(f_\lambda\)-closure of \(S_0\). Provided \(\rho\) is “random,” \(f_\lambda\) acts like a random function on \(S_0\). If \(\Pi\) is closed, then \(|S_0\| \leq K\). If \(\Pi\) is chosen at random, then we expect \(|S_0\| \geq M^t\). Hence, if \(\Pi\) is closed we expect the pseudorandom walk to cycle in approximately \(\sqrt{K}\) steps, but if \(\Pi\) is chosen at random we expect the walk to cycle in approximately \(M^{t/2}\) steps. The constant \(l\) should be selected so that \(M^{l/2}\) is sufficiently larger than \(\sqrt{K}\) (to apply the test to DES, \(l = 1\) suffices).

**Proposition 4.2.** Let \(\omega\) be the statistic computed by CCT and let \(r\) be any positive integer. If \(\Pi\) is closed, then \(P(\omega > \rho) \leq e^{-r/2(M\omega)}\). If \(\Pi\) is chosen at random, then \(P(\omega > \rho) \approx e^{-r/2(2M\omega)}\).

**Proof.** CCT computes a sequence of message vectors \(x_0, \hat{x}_1, \ldots \in \mathcal{M}^t\). More specifically, for each \(i \geq 0\), it is true that \(x_t \approx B\), where \(B\) is the set \(B = \{y : \exists g \in G_{\mathcal{X}}. y = g(x_0)\}\) for some \(g \in G_{\mathcal{X}}\). The group generated by \(G_{\mathcal{X}}\).

If \(\Pi\) is closed, then \(|B| \leq K\). In this case we can model the pseudorandom walk \(x_0, \hat{x}_1, \ldots \) as a discrete finite Markov Process with a \(|B| \times |B|\) transition matrix \(A\).

For each \(1 \leq i, j \leq |B|\), the \((i, j)\)th entry \(a_{ij}\) of \(A\) denotes the probability of selecting \(x_i\), next, given that \(x_j\) was the last selected message vector. Each pseudorandom selection depends only on the immediately preceding message vector. Moreover, for any message vectors \(\hat{x}, \hat{y} \in B\), there is some key \(k\) such that \(T_k(x) = \hat{y}\). Therefore, each entry of \(A\) is at least \(1/K\). Thus, for any positive integer \(r\), the probability of a pseudorandom walk not cycling \(r\) steps is at most \((K/K)^r\).

If \(G_{\mathcal{X}}\) is chosen at random, then the walk in \(G_{\mathcal{X}}\) induces a pseudorandom walk in \(\mathcal{M}^t\).

We now explain how to interpret CCT experiments in light of the two hypotheses \(H_0\) and \(H_\omega\). The evidence obtained from CCT is the value of the statistic \(\omega\). From this evidence, a Bayesian would update his or her odds in favor of \(H_0\) over \(H_\omega\) by
a factor of $p_0/p_K$, where $p_0 = P(\omega = r|H_0)$ and $p_K = P(\omega = r|H_K)$ and $r$ is the observed value of $\omega$.

We now estimate the density functions $p_0$ and $p_K$. By Proposition 4.2 we know that, for any $r$,

$$P(\omega > r|H_K) \leq e^{-r^{3/2}}$$  
(7)

and

$$P(\omega > r|H_0) \approx e^{-r^{3/2}}$$  
(8)

where $c_1 > 0$ and $c_2 > 0$ are defined by $r = c_1 \sqrt{K} = c_2 M^{3/2}$. Hence, $P(\omega \leq r|H_0) \leq 1 - e^{-r^{3/2}}$ and $P(\omega \leq r|H_K) \approx 1 - e^{-r^{3/2}}$.

The density function $p_0$ can be obtained by differentiating the distribution function obtained from equation (8) with respect to $r$. Thus,

$$p_0 \approx \frac{\frac{d}{dr}(1 - e^{-r^{3/2}})}{\frac{d}{dr} e^{-r^{3/2}}} = \frac{c_1 \cdot e^{-r^{3/2}}}{M^{3/2} \cdot e^{-r^{3/2}}} = \frac{c_1}{M^{3/2}} \cdot r^{-3/2}.$$  
(9)

Since equation (7) gives only an upper bound (and not an approximation) of $P(\omega > r|H_K)$, computing $p_0$ is more involved than computing $p_K$. For simplicity, we use the coarse bound

$$p_0 \leq P(\omega \geq r|H_0) \approx P(\omega > r|H_0) \leq e^{-r^{3/2}},$$  
(10)

which is sufficiently powerful to interpret results of CCT. We leave as an open problem how to compute $p_0$ more exactly.

Thus, the ratio $p_0/p_K$ is bounded by

$$\frac{p_0}{p_K} \leq \frac{e^{-r^{3/2}}}{e^{-r^{3/2}}} \cdot \frac{M^{3/2}}{r}.$$  
(11)

The validity of the cycling test depends in part on the extent to which the pseudorandom walk behaves like a truly random walk. To increase our confidence that the pseudorandom function does not interact with the cryptosystem in a way that would invalidate the statistical analysis, we recommend that each trial of the experiment be repeated with different types of pseudorandom functions.16 (See Appendix A for a description of the particular pseudorandom functions used in our experiments.)

It is possible for the random walk to cycle prematurely if certain special sequences of transformations are chosen during the walk. For example, the cycle will close if the identity transformation is selected, or if a transformation and its inverse are repeated one after the other. In particular, the latter condition happens if a pair of DES keys is selected one after the other. In general, every closing of the cycle reveals an algebraic identity of the cryptosystem. Any short cycle is evidence that $f_B$ has a structure different from that expected from a set of randomly chosen permutations.

---

16 For example, the pseudorandom function might be table look-up into a table of randomly generated values, modification of table look-up in which each input into the table is first XOR'd with the previous output from the table, or DES under a randomly chosen fixed key.
4.4. Additional Algebraic Tests

Although the emphasis of our experiments centered around the cycling closure test, we also carried out five additional cycling tests on DES. This section briefly describes these additional tests, which we call the purity test, orbit test, small subgroup test, extended message space closure test, and reduced message space test. We carried out each of these additional tests using the same special-purpose hardware.

4.4.1. Overview and Motivation. It is important to know if DES is pure for essentially the same reasons that it is important to know if DES is closed. If DES were pure, then Tuchman's multiple encryption scheme would be equivalent to single encryption, and DES would be vulnerable to a known-plaintext attack that runs in $2^{28}$ steps on the average. It is possible that DES is pure, but not closed. Although there is no particular reason to suspect that DES is pure, it is unknown in the open literature if DES has this weakness.

Since any set of DES transformations that generates a small group would suffer the weaknesses of closed ciphers, it is natural to ask: "What is the order of the group generated by $n$ given DES transformations?" We call this question the small subgroup question. Any set of transformations that generates a small group would be vulnerable to our known-plaintext attacks against closed ciphers. In addition, multiple encryption (using either sequential multiple encryption or Tuchman's scheme) involving only transformations from such a set would be equivalent to single encryption from the set. Finally, when used in output-feedback mode with feedback width 64 [62], any transformation from such a set would be at greater risk to produce a key stream with short period. Two of our tests address the small subgroup question for $n = 1, 2$.

To test DES for purity and other algebraic weaknesses, we examined the orbits of subsets of DES transformations on particular messages. Our method was to compute the orbits of single DES transformations and to apply the cycling closure test to subsets of two or more DES transformations. We applied the tests both to randomly chosen transformations and to transformations with special properties (e.g., transformations represented by weak keys). The dominant theme of our tests was to determine if DES has algebraic properties different from those expected from a set of randomly selected permutations.

When applied to any subset $S \subseteq F_n$ of two or more transformations, the cycling closure test computes the $f_c$-closure of some message $x_0$, where $p: A \rightarrow H$ and $H \subseteq A$ is a set of keys that represents $S$ and $f_c$ is the function defined by equation (6).

Since there is an overwhelming chance that even two randomly selected permutations will generate either the alternating group or the symmetric group [3], [16], we did not expect to detect any pairs of DES transformations that generate small groups.

4.4.2. Purity Test. Pick any transformation $T_0 \in F_n$ and apply the cycling closure test to the set $T_0^{-1}F_n$. As explained in Section 3.1, $F_n$ is pure if and only if $T_0^{-1}F_n$ is closed.

4.4.3. Orbit Test. Given any key $k$ and any message $x_0$, compute $x_i = T_i(x_0)$, $i = 1, 2, \ldots$, for a specified number of steps or until a cycle is detected.
The period of this sequence is the length of $T_i$-orbit($x_0$). In other words, if we consider the permutation $T_i$ as a product of disjoint cycles, then the period of the sequence is simply the length of the cycle that contains $x_0$. If this test is run for $r$ steps without detecting a cycle, then $r$ is a lower bound on $\text{order}(T_i)$ and hence on $\text{order}(<T_i>)$. Unlike the function $f_e$ from the cycling closure test, $T_i$ is a permutation.

For a randomly chosen permutation on $\mathcal{M}$, for each $1 \leq l \leq M$, the probability that $x_0$ lies in a cycle of length exactly $l$ is $1/M$, independent of $l$. (23), (44), (32, exercise 3.1.12). Hence, the expected cycle length of the longest cycle of a randomly chosen permutation on $n$ letters is about $0.62n$ (50) for DES, this is about $2^n$. For a randomly chosen permutation on $\mathcal{M}$, the chance that we fall into a cycle of length $2^n$ or less is about $2^{-10(2^n-2d)} = 2^{-2d}$.

It is possible to interpret results of the orbit test to obtain statistical lower bounds on the order of the group generated by DES. Such analysis depends on the structure of the group. For example, the orbit test behaves differently on cyclic groups than on symmetric groups. Consequently, it is useful to combine the orbit test with other algebraic tests, including tests for faithfulness, commutativity, solvability at various levels, and nilpotence at various classes. We leave such analysis as future research.

4.4.4. Small Subgroup Test. Given two distinct keys $i, j \in \mathcal{M}$ and any message $x_0$, apply the cycling closure test to the set $\{T_i, T_j\}$ to obtain a statistical lower bound on the length of the $\langle T_i, T_j \rangle$-orbit of $x_0$.

To increase our likelihood of finding algebraic structure, we carried out the small subgroup test on a highly structured pair of DES transformations—the pair of weak keys consisting of all zeros and all ones. Since each of the weak keys is self-inverse, we implemented this experiment as an orbit test of the composition of these two transformations. Our experiment unexpectedly encountered a short orbit (see Section 6).

4.4.5. Extended Message Space Closure Tests. For any experiment that uses the cycling closure test, perform the cycling closure test with an extended message space $\mathcal{M}^l$ with $l > 1$.

For $l = 1$, the closure test works by computing a statistical lower bound on the length of $\langle T_i \rangle$-orbit($x_0$), which, in turn, yields a lower bound on the order of $\langle T_i \rangle$. Limits on the lower bounds achievable by this test are imposed both by the number of steps the test is carried out for and by the relative sizes of the message space and key space. For all $1 \leq r \leq \sqrt{M}$, if the test is run for $r$ steps without detecting a cycle, then with high probability $\text{order}(\langle T_i \rangle) \geq r$. To use the cycling closure test to obtain statistical lower bounds on $\text{order}(\langle T_i \rangle)$ greater than $2^n$, it is necessary to perform an extended message test with $l > 1$.

4.4.6. Reduced Message Space Tests. Perform each of the above tests on a modified version of DES in which the message space is reduced in size. Specifically, consider DES-derived functions $\phi_r: \mathcal{M} \rightarrow \mathcal{M}$ on the reduced message space $\mathcal{M}_r = \{0, 1\}^r$, where $r$ is some small integer (say, $r = 8$) and $\phi_r$ is defined as follows. For each $r$-bit string $x$, define $\phi_r(x)$ by XORing the $r$ least significant bits of $x$ with the $r$ most significant bits of $x$. The Reduced Message Space Test is performed on $\phi_r(x)$, $x \in \mathcal{M}_r$.

\[ \text{See [2] for an approximate probability distribution of the order of elements in } \mathcal{M}. \]
key \( k \in \mathcal{K} \), define \( \phi_k \) by \( \phi_k = \pi_2 T_k \pi_1 \), where \( \pi_1 : \mathcal{P} \rightarrow \mathcal{M} \) is an injection and \( \pi_2 : \mathcal{M} \rightarrow \mathcal{P} \) is a projection. (For example, \( \pi_1 \) might fix the first 56 DES input bits to 0, and \( \pi_2 \) might take only the last 8 DES output bits.)

Studying reduced message space versions of DES is useful for two reasons. First, it is one way to look for structures that may be present on subsets of the message space. Second, by sufficiently restricting the message space, it is possible to write down a complete description of the action of particular transformations on the reduced message space.

5. Attacks Against Group Ciphers

Each of the closure tests can be used with only slight modifications as a known-plaintext attack against any closed cipher. The input to each attack is a short sequence \((p_1, c_1), (p_2, c_2), \ldots, (p_t, c_t)\) of matched plaintext/ciphertext pairs derived from the same secret key \( k \). With high probability each attack finds a representation of \( T_k \) as a product of two or more transformations. The cryptanalyst can use this representation of \( T_k \) to decrypt additional ciphertexts also encrypted under \( k \). The meet-in-the-middle attack requires more space than the cycling attack, but finds a shorter representation of \( T_k \). Neither attack finds \( k \).

5.1. Meet-in-the-Middle Known-Plaintext Attack

The meet-in-the-middle test first picks any message \( p \) and any key \( k \) at random and then computes the ciphertext \( c = T_k(p) \). Next, the test searches for a pair of keys \( a, b \) such that \( T_a = T_b \). Alternately, a cryptanalyst could begin with any matched plaintext/ciphertext pair \((p, c)\) that was encrypted using some unknown key \( k \), and then search for a representation of the secret transformation \( T_k \) as a product \( T_a T_b \). This attack requires \( O(\sqrt{K}) \) time and space on the average. See Fig. 4.

![Fig. 4. Meet-in-the-middle attack against group ciphers.](image-url)
5.2. Cycling Known-Plaintext Attack

The cycling closure test also yields a known-plaintext attack. Given a matched plain-text/ciphertext pair \((p, c)\) that was encrypted under some secret key \(k\), the cryptanalyst computes two pseudorandom walks of the type used in the cycling test, starting from messages \(p\) and \(c\). The same pseudorandom function is used for each of the walks. If the attacked cryptosystem is closed, then, since \(p\) and \(c\) lie in the same orbit, with very high probability the two pseudorandom walks will intersect within about \(\sqrt{K}\) steps. Since the same deterministic pseudorandom function is used for each of the walks, once the two walks intersect, they will forever follow exactly the same path and will therefore drain into the same cycle.

By running the Sedgewick–Szymanski [49] cycle-detection algorithm for each of the pseudorandom walks, and by sharing the same memory for both algorithms, a specific point at which the walks intersect can be found, provided the walks intersect. The two walks can be computed sequentially or simultaneously.

Thus, the cycling test gives a way of generating two sequences of keys \(a_1, a_2, \ldots, a_l\) and \(b_1, b_2, \ldots, b_l\) such that \(g(p) = h(c) = h^{a_l}(p)\), where \(g = T_1 T_2 \cdots T_n\) and \(h = T_n T_{n-1} \cdots T_1\). With high probability, \(T_n = h^{-1} g\), which can be statistically verified by applying \(h^{-1} g\) to additional matched plaintext/ciphertext pairs. If \(T_n \neq h^{-1} g\), then the entire procedure can be repeated on the next plaintext/ciphertext pair. See Fig. 5.

To decrypt each additional ciphertext \(y\), the cryptanalyst computes \(T_n^{-1}(y) = g^{-1} h(y)\). To compute \(h\) in constant space is easy—simply generate the sequence of keys \(b_1, b_2, \ldots, b_l\) by retracing the pseudorandom walk starting from \(c\). The difficulty is to compute \(g^{-1}\) in a time- and space-efficient manner. The problem is that each

![Fig. 5. Cycling known-plaintext attack](image-url)
pseudorandom walk is a "one-way walk" in the sense that reversing any step of the walk requires inverting the encryption function.

One could save each of the keys $a_1, a_2, \ldots, a_e$, but that would require $O(i^2)$ space, where $i$ is the length of the walk starting at $p$. If the attacked cryptosystem is closed, then $i$ will be about $\sqrt{K}$, on the average. On the other hand, one could reverse any step of the walk in constant space by retracing the walk from the beginning, but this procedure would yield an $O(i^2)$-time algorithm for computing $g^{-1}$. Chandra shows that a range of time-space tradeoffs can be used to solve this type of problem. In particular, for any $\epsilon > 0$, it is possible to compute $g^{-1}$ in $O(1/\epsilon)$ space and time $O(1/\epsilon^2)$ [6]. Therefore, if the attacked cryptosystem is closed, then, for any $0 < \epsilon < 1$, the cycling known-plaintext attack can be carried out in space $O(1/\epsilon)$ and time $O(K^{1+\epsilon/2})$, on the average.

5.3. Application of Attacks
Since these attacks can be launched against the group generated by DES, these attacks do not require that DES be closed; they require only that DES generate a small group.

Since DES's relatively small key space of $2^{56}$ keys allows no margin of safety even for 1977 technology [14], these attacks would be a devastating weakness for DES, if DES were a group. In particular, if DES were closed, our IBM personal computer equipped with special-purpose hardware could decrypt DES ciphertexts under the cycling known-plaintext attack in less than 2 hours, on the average (see Section 6).

6. Cycling Experiments on DES

Using a combination of software and special-purpose hardware, we applied the cycling closure test and other algebraic tests to DES. This section describes our experimental work. Section 6.1 summarizes our results. Section 6.2 explains two structural findings. Section 6.3 describes our special-purpose hardware. For more detailed descriptions of our results, see Appendix A.

6.1. Summary of Experimental Results
On April 4, 1985, we completed our first trial of the cycling closure test [30]. This single experiment gives strong evidence that DFS is not closed. During May–August, 1985, we performed additional experiments, including two more closure tests, one extended message space closure test, two purity tests, and two orbit tests [31]. Results from seven of these experiments were consistent with the hypothesis that DES acts like a set of randomly chosen permutations. In particular, these experiments gathered overwhelming evidence that DES is neither closed nor pure. But one orbit experiment involving the composition of two weak keys unexpectedly encountered a small cycle, which was the result of hitting fixed points for each of the weak keys.

Table 1 summarizes our experimental findings. For each experiment, the table lists the approximate leader length and cycle length encountered. The sums of these

* The numbers $p_L$, $p_B$, $p_C$, and $p_F$ are the conditional probabilities of the experimental evidence under the hypotheses "DES is closed (open)" and "each DES transformation was drawn at random from the symmetric group on $\Delta_e$" respectively. The numbers $p_L$ and $p_B$ indicate the chance of encountering a cycle after exactly $r$ steps, where $r$ is the sum of the observed leader and cycle lengths. The numbers $p_C$ and $p_F$ indicate the chance of not encountering a cycle within $r$ steps.  
† Depends on hypothesized group structure.

Lengths form the values of the statistic $\omega$ computed by the tests. The table also lists the conditional probabilities $p_L$, $p_B$, $p_C$, and $p_F$ of the experimental evidence under the hypotheses $H_L$ and $H_F$, respectively. The numbers $p_L$ and $p_B$ are based on probability density calculations and indicate the chance of encountering a cycle after exactly $r$ steps, where $r$ is the observed value of $\omega$. The numbers $p_C$ and $p_F$ are based on probability distribution calculations and indicate the chance of not encountering a cycle within $r$ steps.

For experiments 1, 2, 3, 5, and 6, $p_L$ and $p_B$ were computed from equations (10) and (9), respectively. For these same experiments, as well as for experiment 4, $p_C$ and $p_F$ were computed from equations (7) and (8), respectively. For experiments 7 and 8, the values of $p_L$ and $p_B$ were computed as explained in Section 4.4.3. As explained in Section 4.3, for simplicity, we coarsely bound $p_L$ from above by $p_L$.

In the first cycling closure experiment—which ran for about 2 days—we found a cycle of length exactly $\mu = 7,985,051,916$ with a leader of length $\lambda = 34,293,589$. Let $E$ denote the evidence from our experiment. Since $\mu + \lambda \approx 2^{53} = 2 \lambda / M = 32 / \mu K$, it follows from equation (11) that $P(E|H_L)/P(E|H_F) \leq (e^{-32/\mu} / e^{-2\mu/2}) (2^{64}/2^{23}) \leq e^{-510 \pm 22} \approx e^{-488}$. On the basis of this experiment alone, each reader should decrease his or her odds in favor of $H_L$ over $H_F$ by a factor of about $e^{-488}$. Results of the other closure and purity experiments can be interpreted in a similar fashion.

The second closure experiment produced even stronger evidence that DES is not closed. Moreover, the pseudorandom walks from the first two experiments drained into the same cycles (see Section 6.2.1).

Using 128-bit messages, the extended closure test did not cycle after 2^36 steps, showing that the group generated by DES probably has at least 2^36 elements.

In experiment 7 we computed the orbit of the composition of the two weak keys that consist, respectively, of all zeros and all ones. This experiment produced a short cycle of approximately 2^33 steps, which would be unusual (the probability of encountering a cycle of length at most 2^33 is less than 10^{-9}) if the tested permutation were chosen at random from $\Delta_e$ (see Section 6.2.2).
In experiment 8 we computed the orbit of a randomly chosen transformation for 2 weeks. No cycle was detected after $2^{36}$ steps. This experiment provided no evidence of any algebraic weakness.

In addition, we ran one reduced message space test for which we observed no algebraic weaknesses.

As one test of correctness, we ran a software implementation of the cycling closure test for 30,000 steps. The software and hardware implementations agreed on all values. As a second test of correctness, we repeated each experiment and obtained identical results. We invite the interested reader to verify our results using the detailed experimental data found in Appendix A. Additional analysis by Kaliski further strengthens the reliability of our experimental results [29].

6.2. Two Structural Findings

Although most of our experimental results are consistent with the hypothesis that DES acts like a set of randomly chosen permutations, three experiments did yield interesting regularities. One regularity is a result of the well-known complementation property; the other involves a newly discovered property of the weak keys. We will now explain these structural findings.

6.2.1. Complementation and Drainage Properties. In the first two experiments, we performed two independent trials of the cycling closure test. Each of these experiments used the "identity" next-key function—the function $\rho : M \rightarrow M$ that removes each of the eight parity bits. These two experiments produced two interesting findings. First, each of the pseudorandom walks drained into the same cycle. Second, each point on the cycle was the bitwise complement of the corresponding point exactly halfway around the cycle. Figure 6 illustrates these findings.

The first finding is explained by the fact that, for the graph of a randomly chosen function, most points on the graph will probably drain into the same cycle. (See [26] for one analysis of this phenomenon.)

The second finding is a consequence of DES's complementation property and the fact that the identity next key function also has a complementation property: for all messages $x$, $\rho(x) = \overline{x}$. The cycling closure test computes a pseudorandom walk $x_0, x_1, \ldots$, where $x_{i+1} = T_{\rho(x_i)}(x_i)$ for $i \geq 1$. If $x_i = \overline{x}_j$ for any $i > j$, then it would

![Fig. 6. Results of experiments 1 and 2. Starting at different initial messages, both pseudorandom walks entered the same cycle. Every message on the cycle is the bitwise complement of the corresponding message halfway around the cycle.](image-url)
follow that
\[ x_{h+1} = T_{p_{1+}}(x_h) = T_{p_{2+}}(x_h) = \bar{T}_{p_{1+}}(x_h) = \bar{x}_{h+1}. \] (12)

Therefore, by induction, \( x_{h+k} = \bar{x}_{h+1} \) for all \( h \geq 0 \). This situation arises whenever some \( x_i = x_j \) before any \( x_i = x_i \) with \( i > j \), which will happen for about half of all initial messages.

6.2.2. Fixed Points of the Weak Keys. In experiment 7 we computed the orbit of a message under the composition of the two weak keys that consist, respectively, of all zeros and all ones. Let these two keys be denoted by \( w_0 \) and \( w_1 \), respectively. Although each weak key transformation is self-inverse, we did not expect the composition \( T_{w_0} T_{w_1} \) to produce short orbits. Much to our surprise we detected a cycle of length less than \( 2^{23} \). We presented this finding at the Crypto 85 conference and sought a simple explanation.

After some thought, Don Coppersmith suggested that we had encountered fixed points of the weak keys, i.e., messages \( x, y \) for which \( T_{w_0}(x) = x \) and \( T_{w_1}(y) = y \).

Figure 7 illustrates the effect of the fixed points on experiment 7 and explains why a cycle resulted. Experiment 7 computes the \( \psi \)-orbit of an initial message \( x_0 \), where \( \psi = T_{w_0} T_{w_1} \). Let \( x_i = \psi^i(x_0) \) for all \( i \geq 0 \). In Fig. 7 solid circles denote the messages \( x_0, x_1, \ldots \) in the \( \psi \)-orbit of \( x_0 \). Open circles denote intermediate messages \( y_i = T_{w_1}(x_i) \) for all \( i \geq 0 \). After encountering a fixed point for \( T_{w_1} \) on the \( j \)th step \((j \approx 2^{23})\), the walk began to retrace its steps "out of phase" in the sense that \( x_{j+1} = y_{j-1} \), for all \( j \geq 0 \). Continuing in this fashion, the walk passed over the initial message \( x_0 \) in a "hidden crossing" \( y_j = x_0 \), unnoticed during the experiment since the intermediate values \( y_i \) were not examined. After approximately \( 2^{23} \) steps past the hidden crossing, the walk encountered a fixed point for \( T_{w_0} \). Again, the walk retraced its steps, but this time "in phase," finally returning to the initial message \( x_0 \).

As we will show, for each weak key, a fixed point results whenever the \( L \) and \( R \) registers of DES agree after eight rounds.18 Assuming that the distribution of values taken on by the 32-bit \( L \) and \( R \) registers is random after eight rounds, the \( L \)

---

18 The \( L \) and \( R \) registers are commonly used in the definition of DES. See [61] or [12], for example.
and $R$ registers will agree after eight rounds with probability $1/2^{32}$. Hence, since there are $2^{24}$ messages, we expect there to be approximately $2^{24} \cdot 2^{-32} = 2^{22}$ fixed points for each weak key.\(^\text{19}\)

To understand why a fixed point results for each weak key whenever the $L$ and $R$ registers agree after eight rounds, it is helpful to describe DES as a product of permutations

$$T_i = P^{-1} \pi(\pi h_k) \cdots (\pi h_k) P,$$

where $k$ is the 56-bit key, $P$ is the initial permutation, and $k_1, \ldots, k_{16}$ are the sixteen 48-bit round keys derived from $k$. If $k$ is weak, then $k_1 = k_2 = \cdots = k_{16}$. For all $1 \leq i \leq 16$, the $i$th round consists of the permutation $\pi h_k$, where $\pi, h_k: \mathcal{M} \rightarrow \mathcal{M}$. It is especially convenient to define $\pi$ and $h_k$ in terms of their effects on the $L$ and $R$ registers. For any $r, s \in \{0, 1\}^{32}$, $\pi$ is the "swap" function

$$\pi(r, s) = (s, r)$$

and $h_k$ is the function

$$h_k(r, s) = (r \oplus f_k(s), s),$$

where $f$ is DES's nonlinear function defined in [61]. Note that, for all round keys $k_i$, both $\pi$ and $h_k$ are self-inverse.

Let $x$ be any message and let $k$ be any weak key. If, during the computation of $T_i(x)$, the $L$ and $R$ registers agree after eight rounds, then the effect of rounds eight through nine on the computation of $T_i(x)$ is

$$(\pi h_k) (\pi h_k) \pi (\pi h_k) = \pi h_k h_k = n.$$

By similar argument, it then follows that the effect of rounds seven through ten is also $n$. By induction, it follows that the effect of rounds one through sixteen is $\pi$. Hence, $T_i(x) = (P^{-1} \pi \pi P)(x)$. Note that fixed points arise not only when the round keys are equal, but also when they are "palindromic" in the sense that $k_i = k_{17-i}$ for all $1 \leq i \leq 8$.

After the conference we found the fixed points and thus confirmed Coppersmith's hypothesis (see Appendix A). To the best of our knowledge, these fixed points are the first published in the open literature. These fixed points further illustrate the deficiencies of the weak keys.

Coppersmith also suggested that the algebraic structure detected in experiment 7 can be used to prove stronger lower bounds on the size of the group generated by DES. Experiment 7 computed the length, $l$, of the $\psi$-orbit of $x_0$, where $\psi = T_2 T_n$ and $x_0$ is the initial message. Since $l$ divides the order of $\psi$, it follows that $l$ divides the order of the group generated by DES. Therefore, if experiment 7 were repeated $r$ times with different initial messages, and if these experiments yielded orbit lengths $l_1, l_2, \ldots, l_r$, then $\text{lcm}(l_1, l_2, l_3)$ would be a lower bound on the order of the group generated by DES. We have not extended our results in this direction.

Motivated by our findings, Moore and Simmons carried out additional experiments to investigate the cycle structure of the weak and semiweak keys [39].

\(^{19}\) Moore and Simmons have proven a stronger result: for each "palindromic" and "antipalindromic" key, there are exactly $2^{29}$ fixed points [39].
6.3. Cycling Hardware

We carried out each experiment on a IBM Personal Computer equipped with special-purpose hardware. Our hardware can compute a sequence of 2^{32} DES encryptions per day, where at each step the previous ciphertext is encrypted under a key that depends on the previous ciphertext. This section gives a summary description of our cycling hardware.\textsuperscript{20}

Our goal was to implement the cycling closure test in the simplest way that would enable us to carry out each trial of the experiment within a few days. For each experiment we needed to compute about 2^{12} encryptions, changing the key at each step. For this application, software implementations of DES are too slow.\textsuperscript{21} Moreover, commercially available DES boards are not suited for our purposes: to compute and load a new key for each encryption would require interaction by the host computer, introducing tremendous overhead. Therefore, we built our own hardware.

Our cycling hardware is a custom wire-wrap board for an IBM personal computer.\textsuperscript{22} Our board contains a microprogrammed 7.1 MHz 32-bit finite-state controller and a single 3.6 MHz AMD AmZ8068 DES chip [54]. Data paths 8 bits wide connect the finite-state controller, the DES chip, a 16-byte buffer, a PROM computing the next-key function, an 8-bit counter, and the PC Bus interface to the host computer. To increase the board's flexibility, the controller's microprogram is stored in RAM accessible to the host computer. Figure 8 shows a simplified block diagram of our special-purpose hardware.

Each algebraic test is programmed in microcode for the board's finite-state controller. The next-key function is computed in a byte-by-byte fashion using a PROM, which can be easily replaced to implement different next-key functions. A read-write counter indicates the number of consecutive messages to compute. By periodically reading the board's counter, the host computer detects completion of the board's activity. Our board also supports all approved modes of operation for DES.

We performed cycle detection in two passes: data acquisition and analysis. During data acquisition, the host computer stored every 2^{20}th message on a floppy disk. During analysis, these messages were loaded into main memory, and up to 2^{20} consecutive messages were computed and compared with those already present. In effect we performed the Sedgewick–Szymanski algorithm [49] with a fixed estimate of the cycle length. We used an open-addressing, double-hashing scheme for stores and lookups [33]. All data acquisition and analysis routines were written in the C programming language.\textsuperscript{23}

\textsuperscript{20} See [29] for a complete description and schematic diagrams of our hardware.
\textsuperscript{21} Software implementations of the DES for the IBM PC run at about 200–300 encryptions/second. According to Davio, by using a space-intensive implementation of DES, it is possible to perform about 2.5K encryptions/second on the VAX 11/780 [13]. Thus, it would take the IBM PC about 10–16 days to compute 2^{50} DES encryptions; a VAX 11/780 would require about a day and a half. Running the test for 2^{55} steps would take at least 16 times longer.

\textsuperscript{22} We chose to use an IBM PC because an IBM PC was available to us, and because it is easy to attach special-purpose hardware to an IBM PC [65].

\textsuperscript{23} See [27] for a complete description and listing of all supporting software.
Using cipher-block chaining in direct control mode [54], the AmZ8068 chip is capable of performing approximately 200K encryptions/second. But, for simplicity, we ran our experiments using electronic-codebook mode. We clocked our control loop at 140 ns and the inner encryption loop at 280 ns. Including all overhead for computing and loading a new key for each encryption, our board performed approximately 43K encryptions/second, or about $2^{25}$ per day. This enabled us to carry out each trial of the experiment within a few days.

7. Conclusion and Open Problems

We have developed two statistical tests for determining if a cryptosystem is closed under functional composition, and we have shown how each of these tests yields a known plaintext attack against any group cipher. Moreover, by applying the cycling closure test to DES we have shown, with overwhelming confidence, that DES is neither closed nor pure. In the process we discovered fixed points for the weak keys. Although we had not expected to find fixed points for the weak keys, our experiments otherwise confirmed our expectations: we showed that DES is free of certain gross algebraic weaknesses, and we uncovered an additional weakness of a set of DES transformations already known to be weak.

Our tests are sufficient for determining whether or not DES is closed, but we do not know if the cycling closure test is the most efficient closure test either for DES or for cryptosystems in general. In particular, we do not know if the cycling closure test is an optimal solution to the Group Detection Problem, as formulated by
Is the Data Encryption Standard a Group? 29

Sherman [51]. To settle this question, it would be interesting to analyze the orbit test further.

Although our known-plaintext attacks can be applied against any group cipher, and although it would be a devastating weakness for DES to be a group, it would be wrong to infer that all group ciphers are insecure. For example, the RSA cryptosystem [45] is also vulnerable to our attacks, since the cryptanalyst can proceed as if he were attacking the common modulus RSA cryptosystem, which is a group cipher.24 However, such attacks are less efficient at breaking RSA than are attacks based on known factoring techniques [42], [35]. We view the RSA cryptosystem as evidence that, provided the key space is large enough to withstand our attacks, group ciphers are not necessarily insecure.

Similarly, it would be wrong to conclude that all algebraic properties of cryptosystems are necessarily bad. Our attacks show that, for any group cipher, there is a short-cut solution over exhaustive search of the key space, under a known-plaintext attack. Even though algebraic properties can give the cryptanalyst something to exploit, algebraic properties can also endow a cryptosystem with desirable capabilities or security properties. For example, the rich algebraic structure in the RSA cryptosystem makes it possible to perform public-key cryptography, to compute digital signatures, and to prove a double-edged "bit-security" property [7]. Although there are general relationships between algebraic and security properties of cryptosystems, how algebraic structure affects a cryptosystem depends in part on the particular cryptosystem.

We conclude by listing several open questions about the algebraic structure of DES:

- Does DES generate \(\mathcal{A}_g\)? What is the order of the group generated by DES? What is the group generated by DES? For how many keys \(i, j, k\) is it true that \(T_i = T_j T_k\)?
- Is DES faithful? How many distinct transformations are represented by the DES keys?
- What subsets of DES transformations generate small groups? (Note that each weak key represents a transformation that generates the cyclic group of order 2).
- Is DES homogeneous in the sense that for every \(k \in \mathcal{K}\) it is true that \(T_k^{-1} \in \mathcal{F}_{\text{DES}}\)? For how many \(k \in \mathcal{K}\) is it true that \(T_k^{-1} \in \mathcal{F}_{\text{DES}}\)?
- Is \(I \in \mathcal{F}_{\text{DES}}\)?

Our results show that the composition of every pair of weak keys will likely have a short orbit for every message. It would also be interesting to know if other special pairs of DES transformations have similar properties. For example, it would be interesting to explore semiweak keys, light keys (keys with a low density of ones), heavy keys (keys with a high density of ones), and pairs of related keys (e.g., keys that differ in exactly one bit and keys that are complements of each other).

Knowing whether or not \(I \in \mathcal{F}_{\text{DES}}\) is interesting—not because this property would necessarily be a weakness in DES—but because this question would answer several

24 The common modulus RSA cryptosystem is a variation of the RSA cryptosystem in which the same modulus is used for every key.
other questions about DES. By the complementation property, for any key $k$, $T_k = \overline{T}_k$ implies $T_k = I$. Hence, if $I \in \mathcal{F}_{\text{DES}}$, then DES is not faithful. In particular, if DES is closed, then DES is not faithful. Conversely, if $I \notin \mathcal{F}_{\text{DES}}$, then DES is not closed.

Each of the known-plaintext attacks finds a representation of the secret transformation $T$ as a product of two or more transformations. In practice, it would suffice to find an approximate representation of $T$. To this end we could say that two permutations $T_i, T_j \in \mathcal{F}_{\text{DES}}$ are $q$-approximately equal on $X \subseteq \mathcal{X}$ if and only if, for all $x \in X$, $T_i(x)$ and $T_j(x)$ always agree on at least $q$ bits.

- For each $1 \leq q \leq 64$, for how many keys $i,j,k$ is it true that $T_i$ is $q$-approximately equal to $T_j T_k$ on $\mathcal{X}$?

- What other notions of “approximately equal” transformations would be useful in finding approximate representations?

Since our closure tests do not depend on the detailed definition of DES, it is natural to ask:

- What can be proven from the detailed definition of DES about the order of the group generated by DES?

- Are there more powerful statistical closure tests than the two tests presented in this paper that are based on the detailed definition of DES?

Our research also raises questions involving the design of cryptosystems:

- It is possible to build a secure, practical cryptosystem for which it can be proven that the cryptosystem generates either $\mathcal{S}_a$ or $\mathcal{G}_a$? (See [8] for one suggestion.)

- Is it possible to hide a trapdoor in a cryptosystem by concealing a secret set of generators for a small group? (Note that it does not work simply to have a large subset of the transformations generate a small group, since the enemy could guess a small number of transformations in the subset and apply the cycling closure test to the guessed transformations.)

We presented two known-plaintext attacks against closed ciphers, but other attacks may also exist.

- What attacks are possible against closed ciphers? How can knowledge of the specific group help?

Finally, it would be interesting to apply the closure tests to variations of DES that exaggerate certain types of possible weaknesses in the standard.

- What is the order of “crippled” DES transformations formed by reducing the number of rounds or by replacing one or more of the S-boxes with linear mappings?

Acknowledgments

We would like to thank several people who contributed to this research. Leon Roisenberg assisted Burt with the design and construction of the cycling hardware, and John Hinddale wrote some of the supporting software. The cycling hardware was built in the hardware laboratory of the Functional Languages and Architecture Research Group at the MIT Laboratory for Computer Science. All experiments were carried out on an IBM Personal Computer, which was one of several denoted
by the International Business Machines Corporation to the MIT Laboratory for Computer Science. In addition, we are grateful to László Babai, Don Coppersmith, and Gary Miller for helpful comments.

Appendix A: Detailed Descriptions of Experiments

This appendix presents detailed descriptions of the eight cycling experiments we carried out during April–August, 1985. The appendix begins with an explanation of the next-key functions used in our experiments; the rest of the appendix consists of nine tables that thoroughly document our experiments.

Notation

In Section 1 we defined the key space of DES to be the set $\mathcal{K} = \{0, 1\}^{56}$. Most DES implementations, however, nominally treat each key as a string of 64 bits, where every eighth key bit is a parity bit which is ignored. In this appendix we too shall specify keys and messages as 64-bit strings, described in hexadecimal notation. To do this, it is convenient to introduce the DES function $\mathcal{T}: \mathcal{X} \times \mathcal{M} \to \mathcal{M}$ that operates on the nominal key space $\mathcal{X} = \{0, 1\}^{64}$.

Next-Key Functions

The cycling closure test depends on a function $\rho: \mathcal{M} \to \mathcal{X}$ to compute the next-key from the current message. We will now describe the two particular next-key functions that we used in our experiments. We will define each next-key function in terms of its related function $\beta: \mathcal{M} \to \mathcal{X}$.

Each next-key function operated in a byte-by-byte fashion using a byte substitution table (1 byte = 8 bits). For any $0 \leq i \leq 7$ and any $x \in \mathcal{M}$, let $x^{(i)}$ denote the $i$th byte of $x$. For each $0 \leq i \leq 7$, we computed $\beta(x^{(i)}) = S(x^{(i)})$, for some byte substitution table $S: \{0, 1\}^8 \to \{0, 1\}^8$.

In experiments 1 and 2 we chose $S$ to be the identity function. In the other cycling closure experiments we used the byte substitution table given by Table 2. This table was designed so that each entry has odd parity and such that each entry appears exactly twice. The table was generated using the random number generator in the C library on our IBM PC.

For the experiments that used the extended message space $\mathcal{M}^2$, we computed $\beta(x^{(i)}) = S(x^{(2i)})$ using the substitution table given in Table 2.

Detailed Experimental Results

Tables 2–10 give thorough descriptions and results of our cycling experiments. Table 2 defines the pseudorandom next-key function used in several of the experiments. The remaining eight tables—one for each experiment—list all relevant experimental parameters together with important checkpoints encountered during the experiments. Initial messages and keys were chosen in a variety of ad hoc ways.

---

23 The substitution table is used as follows. To substitute any byte $B$, consider the representation of $B$ as two hexadecimal digits. Select the table entry whose row is given by the first digit and whose column is given by the second digit.
Table 2. Byte substitution table for pseudorandom next-key function.
