

Lecture 10:

Lower bounds via Yao's method

How to prove lower bounds?

Big difficulty: Property testing algorithms are randomized

how do you argue about their behavior?

Useful tool for lower bounding randomized algorithms:

Yao's Principle

If there is probability distribution D
 on union of "positive" ("yes"/"pass") + "negative" ("no"/"fail")
 inputs, s.t. any deterministic algorithm
 of query complexity $\leq t$ outputs in correct
 answer with prob $\geq \frac{1}{3}$ for inputs chosen according to D ,
 then t is a lower bound on the randomized
 query complexity.

moral: average case deterministic lb. \Rightarrow
 randomized worst case l.b.

principle works for
 all types of
 randomized algorithms

Why?

proof omitted

Game theoretic view:

Alice selects deterministic algorithm A } payoff = cost of $A(x)$
 Bob selects input x

Von Neuman's minimax \Rightarrow Bob has randomized strategy which is as good when A randomized

An example:

$$L_n = \left\{ w \mid \begin{array}{l} w \text{ is } n\text{-bit string} \\ w = vv^R ww^R \end{array} \right\}$$

w is concatenation of palindromes

Note: testing if w is ϵ -close to a palindrome i.e. $w = vv^R$ can be done with $O(\frac{1}{\epsilon})$ queries

def w is " ϵ -close to L_n " if $\exists w' \in L_n$

st. w & w' differ on $\leq \epsilon \cdot n$ characters
 (this is different from edit distance)

Thm if A satisfies

$$\forall x \in L_n, \Pr[A(x) = \text{Pass}] \geq 2/3$$

$$\forall x \text{ } \epsilon\text{-far from } L_n, \Pr[A(x) = \text{fail}] \geq 2/3$$

then A makes $\Omega(\frac{1}{\epsilon})$ queries

Proof

Plan: give distribution on inputs that is hard
for all det. algs with $o(\sqrt{n})$ queries.
then Yao \Rightarrow randomized l.b. of $\Omega(\sqrt{n})$

• wlog. assume b/n

• distribution on negative inputs: ← should output "Fail" on these

$N =$ random string of distance $\geq \epsilon n$ from L_n

• distribution on positive inputs:

$P =$ {

1. pick $K \in_R [\frac{n}{b+1}, \frac{n}{3}]$
2. pick random V, u st.
 - $|V| = K$
 - $|u| = \frac{n-2K}{2}$

← should output "Pass" on these

3. output $VV^K u u^K$

← note: some strings can be generated via ≥ 1 K .

• distribution D :

• flip coin

• if H output according to N

else

" " " P

Assume deterministic algorithm A uses $\leq t = O(\sqrt{n})$ queries

Query Tree

depth t
 $\leq 2^t$ root-leaf paths
 wlog all leaves have depth t

output leaves labelled with A 's answer following path + seeing bits labelling edges

NOTE: we can calculate probability of reaching leaf since we know input distribution

Error of leaf: $E^-(l) = \{ \text{inputs } w \in \{0,1\}^n \mid w \text{ } \epsilon\text{-far} + w \text{ reaches leaf } l \}$
 $E^+(l) = \{ \text{inputs } w \in \{0,1\}^n \mid w \in L + w \text{ reaches leaf } l \}$
 ↘ should fail
 ↙ w should pass

Total error of A on D

$$= \sum_{\substack{l \\ \text{passing}}} \Pr_{w \in D} [w \in E^-(l)] + \sum_{\substack{l \\ \text{failing}}} \Pr_{w \in D} [w \in E^+(l)]$$

should fail
but reach passing leaf

should pass
but reach failing leaf

Why is there a problem?

lots of inputs from $N + P$ end up at all leaves.

Claim 1 if $t = o(n)$, $\forall l$ at depth t

$$\Pr_D [w \in E^-(l)] \geq \left(\frac{1}{2} - o(1)\right) 2^{-t}$$

but, each leaf only has 1 label so almost $\frac{1}{2}$ will get wrong label.

Claim 2 if $t = o(\sqrt{n})$, $\forall l$ at depth t

$$\Pr_D [w \in E^+(l)] \geq \left(\frac{1}{2} - o(1)\right) 2^{-t}$$

So error of A on D

$$= \sum_{\substack{l \\ \text{passing}}} \left(\frac{1}{2} - o(1)\right) 2^{-t} + \sum_{\substack{l \\ \text{failing}}} \left(\frac{1}{2} - o(1)\right) 2^{-t} \geq \frac{1}{2} - o(1) \gg \frac{1}{3}$$

still need to prove the claims...

Pf of Claim 1:

idea: N is close to U

+ U would end up uniformly distributed at each leaf

$$\Rightarrow P_{w \in U} [w \in E^{-1}(l)] = \frac{2^{n-t}}{2^n} = 2^{-t}$$

How much can distribution change by using N instead of U ?

$$|L_n| \leq 2^{\frac{n}{2}} \cdot \frac{n}{2}$$

\uparrow choice of u, v \nwarrow choice of i

words at dist $\leq \epsilon$ from L_n :

$$\leq 2^{\frac{n}{2}} \cdot \frac{n}{2} \cdot \sum_{i=0}^{\epsilon n} \binom{n}{i} \leq 2^{\frac{n}{2} + 2\epsilon \log(\frac{1}{\epsilon})n}$$

$$\text{so } E^{-1}(l) \geq 2^{n-t} - 2^{\frac{n}{2} + 2\epsilon \log(\frac{1}{\epsilon})n} = (1 - o(1)) 2^{n-t}$$

\uparrow
strings
in U that
reach l

\uparrow
words at dist $\leq \epsilon$
assume $\epsilon \ll 1/8$
 ϵ is $o(1)$
so 1st term swamps 2nd term!

$$\text{So } P_{N_D} [w \in E^{-1}(l)] \geq \frac{1}{2} P_{N_D} [w \in E^{-1}(l)]$$

$$\geq \frac{1}{2} \frac{|E^{-1}(l)|}{2^n} \geq \left(\frac{1}{2} - o(1)\right) 2^{-t}$$

Proof of Claim 2

Will show: For every fixed set of $o(\sqrt{n})$ queries, lots of strings in L_n follow that path.

Count # strings agreeing with t queries of leaf?

$$= 2^{n-t}$$

Count # strings in L_n agreeing with t queries of leaf?

$$\geq 2^{n-t} - ?$$

Main difficulty:

Fix $k=10$

should see same value at locns:

- 1, 10
- 2, 9
- 3, 8
- 4, 7
- 5, 6
- n, n
- 12, $n-1$
- ⋮
- ⋮

☹ maybe no string in L_n follows path?

😊 that's why k is picked randomly in $[\frac{n}{6} \dots \frac{n}{3}]$!
not all queries can be bad

Given leaf l , let $Q_l \leftarrow$ indices queried along the way

For each of $\binom{t}{2}$ pairs of queries $q_1, q_2 \in Q_l$

at most 2 choices of k for which q_1, q_2 is symmetric to k or $\frac{n}{2} + k$

only 1 choice in this case!

\Rightarrow # choices of k st. no pair in Q_l symmetric around k or $\frac{n}{2} + k$ is

$$\geq \frac{n}{b} - 2 \cdot \binom{t}{2} = (1 - o(1)) \left(\frac{n}{b}\right)$$

For these good k , # strings that follow path = $2^{\frac{n}{2} - t}$

$$\text{So } \Pr_p[w \in E^+(l)] = \sum_w \sum_k \underbrace{\Pr_p[w|k]}_{2^{-n/2}} \underbrace{\Pr[\text{choose } k]}_{\frac{b}{n}} \cdot \mathbb{1}_{w \in E^+(l)}$$

$$\geq \frac{1}{\binom{n}{b} (2^{\frac{n}{2}})} \left[(1 - o(1)) \cdot \frac{n}{b} \right] \cdot 2^{\frac{n}{2} - t} = (1 - o(1)) \cdot 2^{-t}$$

$$\Rightarrow \Pr_0[w \in E^+(l)] = \left(\frac{1}{2} - o(1)\right) 2^{-t}$$
