Identification

Overview of Process Wait and Notify
R. L. Rappaport, Michael J. Spier

Purpose

Processes executing in behalf of the system in the hardcore ring sometimes have to abandon their current processor and revert to the "waiting" state, waiting for some system-event (such as the unlocking of a system-wide data base, or the arrival of a page from the drum) to happen. The Traffic Controller subroutines wait, notify, and addevent provide the mechanism by which a process can either enter the waiting state (wait) or release some other process from that state and put it back on the ready-list (notify).

Introduction

The Traffic Controller's interprocess communication entries block and wakeup (see BJ.3) provide the means necessary in order to allow a process to either give its processor away or to restore another process into the ready-list. Theoretically, subroutines block and wakeup would suffice to handle all cases of process wait and notify; however, experience has shown that block and wakeup are in themselves too primitive, functionally, and that to have a Process Wait and Notify (PWN) mechanism that makes use of these primitives was too costly from an efficiency point of view.

To be specific, the purpose of the PWN module is to "keep book" on all waiting processes, to remember which process is waiting for what event and to make sure that whenever a certain event happens, only the processes that are actually waiting for that event be "notified". PWN is concerned with "system events" (e.g., the unlocking of a system table, the arrival of a page from the drum) which are guaranteed to happen within a predictable period of time, normally measured in milliseconds. The main reason for having a process go into the waiting state is that of maintaining efficient processor-resource management. The cost of going to wait must be fractional compared with the amount of processor time saved. An additional characteristic of system events is that a process will never wait for more than a single system-event at a time.
Consequently, the cheapest way to provide a PWN facility is to thread the waiting-process' APT entry into a wait-list associated with a specific event, and to associate the head of that list with the event name so as to allow the notifying process to find the list and restore the waiting processes into the ready state.

The Process Wait Table (PWT, see BJ.1.03) is a table containing a group of relative pointers to a collection of event threads running through the APT. It is a wired-down table in segment <tc_data> and its size is an agreed-upon constant (actually a prime number, to facilitate hash-lookup.)

Let us suppose that there are N entries in the table. Events are communicated to PWN by name and all processes waiting for an event named A will be hanging off the thread pointed at by a PWT entry associated with A. In order not to have to provide a unique PWT entry for each possible system-event, we must perform a mapping from the set of all possible event names into the set of integers from 1 to N (table size.) In this way, processes waiting for events A and A' may both be placed on the same thread and may be notified incorrectly that their event has occurred. However, if the PWT table size is large compared to the number of loaded processes (which alone may wait for a system-event) and the mapping from event names to numbers is done so as to evenly distribute the names over the numbers, the conflicts should be kept to a minimum.

A call to wait is considered to be "involuntary" from the process' point of view, because it is assumed that more often than not a process will be waiting for the arrival of a page into core; the process gives the processor away for reasons of system efficiency, yet were it not for the missing page it would be capable of doing some useful work for itself. In recognition of this fact, when a waiting process gets notified, it is put at the head of its corresponding queue on the ready list, thus giving it priority over all other processes in that queue. Also, for the same reason, waiting processes do not lose their eligibility (see BJ.6).

The above-described strategy is designed to assure the smoothest and most efficient processor-resource management whenever a process is executing in the hardcore ring; this is of utmost importance considering the fact that a process may spend an estimated half of its virtual processor time in ring 0.
Implementation

An entry in the PWT contains two items, a pointer to the head of the event list (which may assume a zero-value if there is no list) and a flag (which may assume one of the two values ON/OFF).

A PWT entry is said to be inactive if its pointer is of zero-value and its flag is set to off; otherwise it is said to be active.

inactive = (pointer=0) and (flag=off)
active ≠ inactive

Depending upon the state of an entry, the three PWN subroutines operate according to the following algorithm:

ADDEVENT (A) always sets entry A's flag to ON
WAIT (A) if A inactive: returns
if A active: puts itself on thread A, abandons processor
NOTIFY (A) if A inactive: returns
if A active: de-activates A, puts all waiting processes on ready list

A typical way of using the PWN facility is outlined below:

At some point in a computation we reach a point where we do not wish to continue until a particular condition is satisfied. Therefore we perform a test to see if the condition is satisfied; if yes, we simply continue and if not we arrange to wait for the condition to change in the following way. Starting from the original test:

1. Test condition. If true go to step 5.
2. If not true call addevent to activate event.
3. Test condition again. If still not true call wait and upon return go to step 1.
4. If the retest was successful call notify to de-activate the event and possibly wake up waiting processes.
5. Continue.
Sometimes in a computation we become aware of a condition in which others may be interested. In this case we call notify to "broadcast" the good news.

The test of whether or not an event is active provides an interaction between subroutines wait and notify. Without it, it would be possible for a process to put itself on an event-list and give its processor away right after that event was notified by some other process. If this were the last time for this event ever to occur, the waiting process would never run again. According to the PWN algorithm, notify deactivates the event. A process calls wait only after it has previously called addevent, which activates the event. When the process calls wait and finds the event inactive, it knows that someone has notified all the processes waiting for that event and consequently immediately returns.

The three PWN subroutines are described in detail in sections BJ.2.01-03, respectively.
